Author: Parth Shah

Title: Chapter 2 Solutions

Notes

Insertion Sort pseudocode. Insertion sort basically works by swapping elements into the right place. It starts with the second element and increments to the end.

```
1: procedure Insertion Sort(A)
      for j = 2 to A.length do
2:
         key = A[j]
3:
         i = j - 1
4:
         while i > 0 and A[i] > key do
5:
             A[i+1] = A[i]
6:
             i = i - 1
7:
         A[i+1] = key
8:
      return A
9:
```

Merge is a method to merge two sorted lists into one sorted list. It is a subroutine of merge sort. The pseudocode is below.

```
1: procedure MERGE(A,p,q,r)
       n_1 = q - p + 1
3:
       n_2 = r - q
       let L[1...n_1 + 1] and R[1...n_2 + 1] be new arrays
 4:
       for i = 1 to n_1 do
 5:
           L[i] = A[p+i-1]
6:
       for j = 1 to n_2 do
7:
           R[j] = A[q+j]
8:
       L[n_1+1] = \infty
9:
       R[n_2+1]=\infty
10:
       i = 1
11:
12:
       j = 1
       for k = p to r do
13:
           if L[i] \leq R[j] then
14:
              A[k] = L[i]
15:
              i = i + 1
16:
17:
           else
18:
              A[k] = R[j]
              j = j + 1
19:
```

Merge Sort uses the merge process and recursively sorts an array. It first divides into two halves, sorts the halves and then merges the two sorted halves.

```
1: procedure MERGESORT(A,p,r)
2: if p < r then
3: q = \lfloor (p+r)/2 \rfloor
4: MergeSort(A, p, q)
5: MergeSort(A, q + 1, r)
6: Merge(A, p, q, r)
```

2.1 Insertion Sort

Problem 2.1-1 Show how insertion sort works on the sequence $A = \{31, 41, 59, 26, 41, 58\}$

Solution 2.1-1

```
1: A = \{31|41, 59, 26, 41, 58\}

2: A = \{31, 41|59, 26, 41, 58\}

3: A = \{31, 41, 59|26, 41, 58\}

4: A = \{31, 41, 59, 26|41, 58\}

5: A = \{31, 41, 26, 59|41, 58\}

6: A = \{31, 26, 41, 59|41, 58\}

7: A = \{26, 31, 41, 59|41, 58\}

8: A = \{26, 31, 41, 59, 41|58\}

9: A = \{26, 31, 41, 41, 59, 58|\}

10: A = \{26, 31, 41, 41, 59, 58|\}

11: A = \{26, 31, 41, 41, 58, 59\}
```

Problem 2.1-2 Rewrite insertion sort to sort in nondecreasing order.

Solution 2.1-2

```
1: procedure Insertion Sort(A)
      for j = 2 to A.length do
3:
         key = A[j]
         i = j - 1
4:
          while i > 0 and A[i] < key do
5:
             A[i+1] = A[i]
6:
             i = i - 1
7:
          A[i+1] = key
8:
      {\bf return}\ A
9:
```

Problem 2.1-3 Consider linear searching problem. Given sequence $A = \langle a_1, a_2, a_3, a_4, ... a_n \rangle$ return index i where value x is located in A. If x is not in A return NIL

```
1: procedure LinearSearch(A,x)
2: for j = 1 to A.length do
3: if x = A[j] then
4: return j
5: return NIL
```

Solution 2.1-3

Problem 2.1-4 Write an algorithm to add 2 n-bit integers A and B to create (n+1)-bit integer C.

Solution 2.1-4

```
1: procedure BITSUM(A,B)
        carrybit = 0
        for j = 1 to n do
3:
           if (carrybit \text{ and } (B[j] \text{ or } A[j])) or (\text{not } carrybit \text{ and } (B[j] \text{ and } A[j]) then carrybit = 1
 4:
               if (carrybit and B[j] and A[j]) then C[j] = 1
5:
               elseC[j] = 0
 6:
           else
 7:
               carrybit = 0
 8:
               if not (carrybit or B[j] or A[j]) then C[j] = 0
9:
               elseC[j] = 1
10:
        C[n+1] = carrybit
11:
        return C
12:
```

2.2 Analyzing Algorithms

Problem 2.2-1 Express function $n^3/1000 - 100n^2 - 100n + 3$ in terms of Θ notation.

Solution 2.2-1 $\Theta(n^3)$

Problem 2.2-2 Selection sort goes in increasing order from 1 to n-1 and finds the i^{th} smallest number and swaps it with A[i]. What loop invariant does selection sort maintain? Why does it only need to run for the first n-1 elements? Best and worst case run-time?

Solution 2.2-2 Selection sort maintains the invariant that elements 1 through i are sorted after the i^{th} iteration. It only needs n-1 elements because then the smallest n-1 elements are sorted which means the last element is in the correct location. Best case run time is $\Theta(n^2)$ and worst case is $\Theta(n^2)$ because it take $\Theta(n)$ to find the i^{th} smallest element.

Problem 2.2-3 In linear search on average how many elements are checked? Worst case? Asymptotic notation for average and worst case?

Solution 2.2-3 Since the element is equally likely to be found at any index, the average number of elements looked is simply the expected index the element is at. This is (n+1)/2. Worst case it looks through all n elements. In asymptotic notation average case is $\Theta(n)$ and worst case is $\Theta(n)$ as well.

Problem 2.2-4 How can we modify any algorithm to have good best case running time?

Solution 2.2-4 Check if input already satisfies the output or some simple condition and then return it. Example in any sorting method check if its already in order and if so return the input. Otherwise sort.

2.3 Designing Algorithms

Problem 2.3-1 Illustrate merge sort operation on $A = \{3, 41, 52, 26, 38, 57, 9, 49\}.$

Solution 2.3-1

```
1: A = \{3, 41, 52, 26 | 38, 57, 9, 49\}

2: B = \{3, 41 | 52, 26\}, C = \{38, 57 | 9, 49\}

3: D = \{3 | 41\}, E = \{52 | 26\}

4: Merge left and right of D and E

5: D = \{3, 41\}, E = \{26, 52\}

6: F = \{38 | 57\}, G = \{9 | 49\}

7: Merge left and right of F and G

8: F = \{38, 57\}, G = \{9, 49\}

9: Merge D and E

10: B = \{3, 26, 41, 52\}

11: Merge F and G

12: C = \{9, 38, 49, 57\}

13: Merge B and C

14: A = \{3, 9, 26, 38, 41, 49, 52, 57\}
```

Problem 2.3-2 Rewrite the merge procedure such that it simply copies the remaining array into A once either L or R are completely copied into A.

Solution 2.3-2

```
1: procedure MERGE(A,p,q,r)
2:
       n_1 = q - p + 1
       n_2 = r - q
3:
       let L[1...n_1] and R[1...n_2] be new arrays
 4:
       for i = 1 to n_1 do
 5:
           L[i] = A[p+i-1]
6:
       for j = 1 to n_2 do
 7:
           R[j] = A[q+j]
8:
       i = 1
9:
       j = 1
10:
11:
       for k = p to r do
12:
           if i = n_1 + 1 then
              A[k...r] = R[j...n_2]
13:
14:
              return
           if j = n_2 + 1 then
15:
              A[k...r] = R[i...n_1]
16:
17:
              return
           if L[i] \leq R[j] then
18:
              A[k] = L[i]
19:
              i = i + 1
20:
           else
21:
               A[k] = R[j]
22:
              j = j + 1
23:
```

Problem 2.3-3 Use induction to show that when n is a power of two the solution to the following recurrence T(n) is $T(n) = n \lg(n)$

$$T(n) = \begin{cases} 2 & n = 2\\ 2T(n/2) + n & n = 2^k, k > 1 \end{cases}$$

Solution 2.3-3 Base case: n=2. $T(2)=2=2\lg(2)$. Hence the base case is true. Now we must show that if for a give $n=2^k$ the recursion is true then it is also true for $n=2^{k+1}$. By the formula $T(2^{k+1})=2T(2^k)+2^{k+1}=2k\cdot 2^k+2^{k+1}=(k+1)2^{k+1}$. This satisfies the equation and therefore the recurrence $T(n)=n\lg(n)$.

Problem 2.3-4 Insertion sort can be expressed recursively. Sort A[1...n-1] and then insert A[n] in proper spot. Write the recurrence for this description of insertion sort.

Solution 2.3-4 The recurrence is $T(n) = T(n-1) + \Theta(n)$.

Problem 2.3-5 Write pseudocode for binary search method on a sorted array. Show that worst case is $\Theta(\lg(n))$

Solution 2.3-5

At each step the search space if halved. So the recurrence is T(n) = T(n/2) + 1 which evaluates to $\Theta(\lg(n))$.

```
1: procedure BINARYSEARCH(A,x,low,high)
       if low = high then
           if A[low] = x then
3:
               return low
 4:
 5:
           else
               return NIL
 6:
       j = \lfloor \frac{low + high}{2} \rfloor
 7:
       if A[j] \leq x then
 8:
           high = j
9:
           BinarySearch(A, x, low, high)
10:
       else
11:
12:
           low = i
13:
           BinarySearch(A, x, low, high)
```

Problem 2.3-6 Insertion sort uses linear scan to find location for each new entry. Can a binary search improve the run time to $\Theta(n \lg(n))$

Solution 2.3-6 No. The key is in swapping. While finding the location to insert it into would be sped up to $O(\lg(n))$ there is no way around the O(n) swaps required to get the new entry into the proper location.

Problem 2.3-7 Describe a $\Theta(n \lg(n))$ solution that given a set S of n integers and a value x finds if a pair of integers in S that sum to x.

Solution 2.3-7 First sort S using merge sort in $\Theta(n \lg(n))$ time. Then for each index i from 1 to n binary search for x - A[i] in sorted array A. If it exists at index j and $j \neq i$ return (i, j). Otherwise return no solution.

Problems

Problem 2-1 Sometimes insertion sort is faster on smaller sequences due to constants involved in the runtime. So often insertion sort is used as a subroutine on the merge sort recursion when the size of the array to be sorted is less than or equal to some size k. Consider a merge sort in which n/k sublists of size k are sorted by insertion sort and then are merged using the standard merge sort procedure.

a) Show that the insertion sort portion runs in $\Theta(nk)$.

Solution Insertion sort on k items runs in worst case Θk^2 . Since there are n/k sublists of k items each the total runtime is $(n/k)k^2 = \Theta(nk)$

b) Show that the merge of the n/k sublists can be done in $\Theta(n \lg(n/k))$

Solution At each level we can merge 2 sublists. So each process requires the merging of n/k elements of k sublists giving a runtime of $\Theta(n)$. Now to combine all n/k into one take $\lg(n/k)$ of these binary merges. Therefore the runtime of the merge is the runtime of a level times the depth which is $\Theta(n \lg(n/k))$.

c) The new algorithm runs in $\Theta(nk + n \lg(n/k))$. What value of k gives the same runtime as merge sort.

Solution $k = O(\lg(n))$

 \mathbf{d}) How should you choose k in practice.

Solution Try multiple values of k on multiple values of n. In fact you can binary search and test on values of k. To speed up the search set a small constant lower bound and an upper bound on order $\lg(n)$. Usually a good k may be the size of a block in your cache.

Problem 2-2

```
1: procedure Bubblesort(A)
2: for i = 1 to A.length do
3: for j = A.length downto i + 1 do
4: if A[j] < A[j - 1] then
5: swap A[j] and A[j - 1]
```

a) To prove Bubblesort is correct we need to show it terminates and that when it does it is in nondecreasing order. What else do we need to show in order to say that bubblesort actually sorts.

Solution We also need to show that values are not somehow changed. The output has the same values as the input.

b) State a loop invariant for lines 2-4 and show it holds.

Solution The invariant is that the minimum A[k] seen is at index j. Prove by induction. Initially only 1 element is seen and therefore it is minimum. It is at index j. If this holds true for j = k + 1 we can show it is true for j = k. If A[k] is less than A[k+1] order remains otherwise they are swapped. Since we are taking the minimum of the two and A[k+1] is the minimum of all previously seen, the invariant is clearly maintained.

c) State a loop invariant for the entire bubble sort.

Solution At the end of each iteration of the for loop all elements A[1] through A[i] are sorted. Prove by induction. This is clearly true in the beginning as 0 elements are sorted. Given the first i-1 elements are sorted we can show after the next iteration i elements will be sorted. Based on the solution to part b, we know that the minimum of all elements in indices i to n will be placed into A[i]. Since the elements A[1] to A[i-1] is less than A[i] the first i elements are now sorted. Therefore the invariant is maintained.

d) Give worst case runtime for bubble sort.

Solution Worst case requires n-i swaps for each iteration of the outer for loop. Summing over all i this gives n(n-1)/2 and hence asymptotic time of $\Theta(n^2)$.

Problem 2-3 Horner's rule is a way to quickly evaluate a polynomial. Instead of evaluating all x^k , Horner's rule recursively multiplies by x and adds a coefficient. By Horner's rule, $P(x) = a_0 + x(a_1 + x(a_2 + ... + xa_n)...)$. Algorithmically it looks as follows:

a) In terms of Θ -notation what is the runtime.

```
1: y = 0
```

2: for i = n downto 0 do

3:
$$y = a_i + x \cdot y$$

Solution The runtime is $\Theta(n)$ because the statement inside the loop is executed n times.

b) Write pseudocode for naive implementation of polynomial evaluation. What is the runtime?

Solution

```
1: val = 0
```

2: for i = n downto 0 do

3: $val = val + a_i x^i$

Evaluating the inner statement takes $\Theta(i)$ time. Summing i from 0 to n we get $\Theta(n^2)$ time.

c) Assume invariant is that for given k, the current evaluation is a factor x^{n-k} off from its final contribution. Prove invariant holds.

Solution Since the component is currently $\sum_{i=0}^{k} a_{n-i}x^{k-i}$. The final contribution will be $\sum_{i=0}^{k} a_{n-i}x^{n-i}$. If we multiply a x^{n-k} we see that the two sums are equivalent.

d) Conclude the method is correct.

Solution Since at each step we scale up and add a new coefficient this process ensures that the coefficient of a_i has been scaled up i times. Which means the a_i coefficient is multiplied by x^i . This is equivalent to the polynomial sum and therefore we see that the method is correct.

Problem 2-4 Inversion are as such. In an array A for indices i and j such that i < j, if A[i] > A[j] there is an inversion.

a) List the five inversions of $\{2, 3, 8, 6, 1\}$

Solution (2,1) (3,1) (8,1) (6,1) (8,6)

b) What array from set $\{1, 2, ..., n\}$

Solution $\{n, n-1, ..., 2, 1\}$. This has $\sum_{i=1}^{n-1} i$ inversions which is equal to n(n-1)/2.

c) What is the relationship between runtime of insertion sort and the number of inversions.

Solution The runtime is equivalent to the number of inversions. For each inversion insertion sort will need to make one swap between those two elements.

d) Give a method to calculate the number of inversions in $\Theta(n \lg(n))$ time.

Solution Use merge sort except modify the merge method. Keep a counter. Every time any merge method takes an element from R before L add the remaining size of R to the counter. This counter is global and at the end the counter is the number of inversions.
